Abstract

Mycotoxin contamination in pet food poses a serious health threat to pets, causing an emotional and economical concern to the pet owners. Aflatoxins, ochratoxins, trichothecenes, zearalenone, fumonisins and fusaric acid have been found in the ingredients and final products of pet food, resulting in both acute toxicity and chronic health problems in pets. Toxicological interaction among mycotoxins as a natural mixture further complicates the issue. The concepts of “risk assessment”, using hazard identification, dose–response assessment, no observable adverse effect level (NOAEL), and lowest observed adverse effect level (LOAEL), should be applied to assess the risk and safety of mycotoxins in pet food, thereby instilling public confidence in the pet food industry.

1. Introduction

Mycotoxin contamination in pet food poses a serious health threat to pets. Cereal grains and nuts are used as ingredients in commercial pet food for companion animals such as cats, dogs, birds, fish, reptiles and rodents. Cereal by-products may be diverted to animal feed even though they can contain mycotoxins at concentrations greater than raw cereals due to processing (Moss, 1996; Brera et al., 2006). Several mycotoxicosis outbreaks in commercial pet food have been reported in the past few years (Garland and Reagor, 2001; Stenske et al., 2006). Most outbreaks of pet mycotoxicosis, however, remain unpublished and may involve the death of hundreds of animals (MSNBC News Services, 2006).

The term “companion animal” implies the existence of a strong human–animal bond between pets and their owners (Adams et al., 2004). A pet is often regarded as a family member by its owner and a person may develop strong relationships with animals throughout his or her lifetime. Pet interactions and ownership have been associated with both emotional and physical health benefits (Milani, 1996; Adams et al., 2004). The human–animal bond has resulted in over sixty four million American households in owning one or more pets, thereby creating a huge market for the pet food industry (APPMA, 2006). Dogs and cats continue to be the most popular pet to own, found in at least one out of three US households. The health problems of pets, are therefore more of an emotional concern as compared to a mainly financial concern in farm animals (Dunn et al., 2005; Milani, 1996).

2. Surveys of mycotoxins in pet food and outbreaks of mycotoxoses in pets

There have been several published mycotoxin surveys of commercial pet foods (Table 1). Aflatoxins, ochratoxins, trichothecenes, zearalenone and fumonisins were detected in food for dogs, cats, birds, rodents and fish with different prevalences across regions. Wild bird seed, for instance, has been found to be most contaminated among different pet food products (Henke et al., 2001).

There has been a recent review of individual cases involving mycotoxins in pets (Leung et al., 2006). Aflatoxins have been the most common cause of acute mycotoxicosis outbreaks in commercial dog food (Table 2). Corn is the usual source of aflatoxins in these cases. An ochratoxicosis outbreak was also reported in Korea with 3 known deaths. These available reports of acute mycotoxicosis,
however, cannot provide the whole picture of the mycotoxin problem associated with pet foods since only a small number of food poisoning cases are published. Veterinarians, furthermore, often overlooked mycotoxins as the cause of chronic diseases such as liver and kidney fibrosis, infections resulting from immunosuppression and cancer. These findings suggest that mycotoxin contamination in pet food poses a serious health threat to pet species.

### 3. Effects of mycotoxins on pet species

#### 3.1. Aflatoxins

Aflatoxins are commonly found in corn, peanuts, cottonseed, milk, and tree nuts (Haschek et al., 2002). Aflatoxins B1, B2, G1 and G2 are four naturally-occurring forms of aflatoxins, with aflatoxin B1 being the most potent, prevalent and carcinogenic (Puschnir, 2002; IARC, 1993). After ingestion, aflatoxins are absorbed and carried to the liver via the circulatory system. They are then converted by the liver into toxic reactive epoxides which bind covalently to intracellular macromolecules such as DNA, RNA and protein enzymes, resulting in damage to liver cells (Cullen and Newberne, 1994). The primary clinical effects in aflatoxicosis are related to hepatic damage in all species studied. In acute aflatoxicosis, dogs exposed to >0.5–1 mg aflatoxin/kg body weight (BW) typically die within days, showing enlarged livers, disseminated intravascular coagulation and internal hemorrhaging (Bohn and Razza-Fazeli, 2005). Sub-acute aflatoxicosis (0.5–1 mg aflatoxin/kg pet food) is characterized by anorexia, lethargy, jaundice, intravascular coagulation and death in 2–3 weeks. Similar hepatotoxic effects can also be produced by chronic aflatoxin exposure with 0.05–0.3 mg aflatoxin/kg pet food over 6–8 weeks.

In addition to their hepatotoxic properties, aflatoxins are also carcinogenic. The binding of DNA causes genotoxicity and mutation in cells. The chronic carcinogenic dose of aflatoxins is

much lower than the acute dose. Newberne and Wogan (1968) have experimentally induced malignant tumors in rats with a continual exposure of <1 mg aflatoxin B<sub>1</sub>/kg feed. Since aflatoxins are both acute and chronic hepatotoxins and carcinogens, the actual number of dogs affected by aflatoxins would be far more than the total number reported in acute poisoning cases.

3.2. Ochratoxins

Ochratoxins are a group of potent renal mycotoxins that widely contaminate the agricultural commodities, such as corn, wheat, oats and dried beans, in temperate regions. There are four ochratoxin homologues — A, B, C and D. Ochratoxin A (OTA) is the most prevalent and, together with ochratoxin C, most toxic. Initial symptoms of ochratoxicosis observed in all species include anorexia, polydipsia, polyuria and dehydration, and are associated with renal damage.

Upon absorption, ochratoxins enter the circulatory system, bind tightly to serum proteins and accumulate in the kidneys, where they disrupt protein synthesis and other pathways in proximal tubular cells. This results in the degeneration of the proximal tubules and interstitial fibroses (Krogh, 1992). OTA is also known to bind with DNA molecules and induce renal tumors in animal models, although its carcinogenic mechanism remains controversial (Faucet et al., 2004; Mally et al., 2004).

Dogs show a high susceptibility to OTA, for example, a daily dose of 0.2 mg OTA/kg BW for 2 weeks or a single dose of 7.8 mg OTA/kg BW was fatal to young beagle dogs (Szczez et al., 1973). Clinical symptoms of the OTA poisoning included anorexia, weight loss, vomiting, tenesmus, bloody diarrhea, increased body temperature, tonsillitis, dehydration, and prostration. These findings were confirmed by a later study in which dogs showed similar symptoms at OTA doses between 0.2 and 3.0 mg/kg BW (Kitchen et al., 1977).

3.3. Trichothecenes

Trichothecenes are a family of Fusarium mycotoxins commonly found in corn, wheat, barley, as well as oats worldwide (Haschek et al., 2002). Over 150 trichothecenes have been identified to date, including deoxynivalenol (DON), nivalenol, diacetylcarpenol (DAS) and T-2 toxin (Pittet, 1998). Although not as toxic as DAS and T-2 toxin, DON is the most important and, together with ochratoxin C, most toxic. Initial symptoms of trichothecene toxicity include anorexia, polydipsia, polyuria and dehydration, and are associated with renal damage.

The influence of trichothecenes on feed intake has been widely studied in a number of animals, including dogs. Hughes et al. (1999) investigated the feed refusal effect of DON on Brittany and Beagle dogs and cats in a two-week clinical feeding trial. It was estimated that 4.5 mg DON/kg pet food produced a significant decrease in feed intake, while vomiting was observed with the exposure of 8 mg DON/kg pet food. Cats were slightly more resistant than dogs. In a recent study, Leung et al. (in press) showed that the exposure of 3 mg DON/kg pet food caused significant weight loss and feed intake reduction in Beagle dogs. The study by Hughes et al. (1999) also showed that the dogs previously exposed to DON were able to preferentially select the uncontaminated diet.

Feed refusal and vomiting, the most notable behavioral effects of trichothecenes, are possibly related to their influences on brain regional neurochemistry and feed intake regulation. There is strong evidence that serotonergic and α2-noradrenergic systems interact antagonistically through medial hypothalamic satiety mechanisms (Leibowitz and Shor-Posner, 1986). In a recent comparative study (Swamy et al., 2004), swine fed with trichothecene-contaminated grains showed a decrease in norepinephrine concentration and increases in serotonergic neurotransmitter concentrations, possibly affecting the antagonistic interaction between these two systems on feed intake. On the other hand, broiler chickens showed increases in both norepinephrine and serotonin concentrations and the antagonistic interaction between the two systems was therefore maintained. This comparison accounts for the species differences in Fusarium mycotoxin susceptibility. Similar mechanistic studies have not been performed in pet species.

The effects of trichothecenes are especially obvious in rapidly dividing cells of the intestinal mucosa and bone marrow. A single oral administration of T-2 toxin was sufficient to induce cell death in the intestinal crypt epithelium at a dose of 2.5 mg T-2/kg BW. A dose of 25 mg/kg BW caused extensive damage to intestinal villi (Li et al., 1997; Haschek et al., 2002). In another study, Coppock et al. (1989) administrated an intravenous dose of 0.5 mg DAS/kg BW to dogs and examined their hematological changes in the following 8 hours. Damage to bone marrow haematopoietic elements and an increase in deformed blood cells were observed. The vulnerability of gastrointestinal and immune systems to trichothecene toxicity accounts for the symptoms of gastrointestinal distress, bloody diarrhea and immune suppression in trichothecene poisoning.

3.4. Zearalenone

Zearalenone is an estrogenic Fusarium mycotoxin found in various cereal crops, most frequently in corn (Cheeke, 1998), causing hyperestrogenism and reproductive problems in all animal species, especially pigs (Bohn and Razza – Fazeli, 2005). Low doses of zearalenone (< 1 mg/kg feed) may cause infertility, affecting ovulation, conception, implantation, fetal development, and the newborn’s viability (Schweighardt, 1980; Price et al., 1993). Zearalenone has structural similarities to estrogen. It can bind to cytosolic estrogen receptors in target cells (Riley and Norred, 1996). The resultant receptor–zearalenone complex activates the transcription of estrogen-responsive genes, causing the translation of new proteins and expressing estrogenic effects upon the target cells. Most clinical signs of zearalenone poisoning are related to the hyperstimulation of estrogen-dependent tissues.
Both male and female dogs are affected by zearalenone toxicity. Hidy et al. (1977) gavaged dogs with 5 mg zearalenone/kg BW/day for 13 weeks. Reduced number of corpora lutea and arrested spermatogenesis were observed in female and male dogs, respectively. Although the dose used by Hidy et al. (1977) was much higher than normal dietary exposure, some recent studies suggested that low levels of zearalenone exposure can also produce significant toxic effects. Female dogs fed 200 μg zearalenone/kg BW/day for 7 days showed cell damage in ovaries; and edema and hyperplasia in oviducts and the uterus (Gajecka et al., 2004a). Dogs also demonstrated a reduction in serum antibodies and white blood cell levels after a 50-day dietary exposure to 25 and 50 μg zearalenone/kg BW/day (Gajecka et al., 2004b). Uterine edema and hyperplasia leads to pyometra, an infection of the uterus, a disease common in female dogs.

3.5. Fumonisins

Fumonisins are found in corn throughout the world with more than 15 homologues isolated, including fumonisin B₁, B₂, B₃, B₄, A₁, and A₂ (Rheeder et al., 1992; Haschek et al., 2002; Scott, 1993). Fumonisins B₁, B₂ and B₃ (FB₁, FB₂ and FB₃) are the most prevalent members and FB₁ represents up to 70% of food-borne fumonisins. Fumonisins are poorly absorbed from the gut and can be inactivated by the gut microflora resulting in large species differences in susceptibility. Once they enter the blood circulation, fumonisins damage numerous organs in all species studied. These mycotoxins are structurally similar to sphingoid bases, inhibiting the activity of ceramide synthase to produce sphingolipids. The disruption of sphingolipid synthesis and metabolism in cells sequentially causes cell damage, apoptosis, necrosis and compensatory hyperplasia (Haschek et al., 2002; Wang et al., 1991). Since fumonisins also inhibit the function of L-type calcium channels, the cardiovascular system is also disturbed. While the liver and kidney are highly susceptible organs to acute fumonisin toxicity, the immune system is mainly affected in chronic fumonisin exposure.

The clinical effects of fumonisins vary between animal species but most toxicology investigations are done on species other than pets. Voss et al. (1998) reported an increased rate of hepatic and renal lesions in rats after a three-week dietary exposure to 32–49 mg FB₁/kg feed. The oral exposure of 1.75 mg FB₁/kg BW/day for 13 weeks was lethal to the Beagles despite a six-month dietary exposure. A series of experiments were conducted by Matsuzaki et al. (1976a,b) who fed young Beagle dogs 50 mg fusaric acid calcium salt (FA-Ca)/kg BW for 30 days and 6 months, respectively. Low appetite, vomiting, suppressed weight gain and hypotension were observed. A six-month exposure of 100 mg FA-Ca/kg BW was lethal to the Beagles, causing significant hypotension and gastrointestinal, hepatic and pulmonary bleeding. Daily doses of 20 mg FA-Ca/kg BW had, however, no effect in general to the Beagles despite a six-month dietary exposure.

4. Multiple simultaneous mycotoxin exposure

Multiple mycotoxin exposure is common in the natural situation. There are four categories describing possible mycotoxin interactions (Eaton and Klaassen, 2001).

1. Additivism — the combined effects of the mycotoxins is equal to the sum of each of the mycotoxins given alone.
2. Synergism — the combined effects of the mycotoxins are much greater than the sum of the effects of each mycotoxin alone.
3. Potentiation — one mycotoxin has no toxic effect on an organ but when added to another mycotoxin makes that mycotoxin much more toxic.
4. Antagonism — two mycotoxins administered together interfere with each other’s actions reducing the toxic effect.

Chemical interactions occur due to alterations in absorption, protein binding, biotransformation, and excretion. Mycotoxins that have a common site of action present the greatest opportunity for a cumulative toxic effect. A toxicological potentiation between DON and fusaric acid, for instance, has been demonstrated in 8 kg piglets where DON toxicity was augmented when fusaric acid was added in diet (Smith et al., 1997). In another study, it was found that chickens fed combinations of DON and T-2 toxin from hatching to three weeks had significantly reduced body weight gain (Kubena et al., 1990). This variable was not reduced, however, when either DON or T-2 toxin were fed singly, thereby suggesting a synergistic interaction. The toxicity of a particular mycotoxin, therefore, depends on not only its own concentration but also the presence of other mycotoxins.

5. Determination of risk and safety

“Risk assessment” is the systematic scientific characterization of potential adverse effects resulting from exposure to hazardous agents (NRC, 1993; Faustman and Omenn, 2001). Risk is the...
probability that a substance will produce a toxic effect. Risk involves two components: toxicity and exposure. Thus mycotoxins of relatively low toxicity may pose significant risks if exposure is great, frequent, and long. Conversely, mycotoxins of high toxicity, such as aflatoxins, may pose virtually no risk if exposure can be substantially reduced. “Exposure assessment” determines what type, levels, and duration of exposures are expected. Although the exposure of pet animals to mycotoxins in grain-based pet food is generally low, it is unavoidable and occurs throughout the entire lifespan of the animal.

The toxicity of a substance is dependent on its chemical, physical and biological properties. Often referred to as “hazard”, toxicity is an inherent property of the compound and the animal being exposed (Faustman and Omenn, 2001). The objectives of classical mammalian toxicity studies developed for risk assessment are as follows:

1. Hazard identification — determine the kinds of adverse effects
2. Dose–response assessment — determine the potency or sensitivity of effects
3. No observable adverse effect level (NOAEL) and lowest observed adverse effect level (LOAEL).

Toxicological information on mycotoxins is important because it allows us to judge the relative risk that may result from exposure to these toxic substances. Today’s short-term repeat dose toxicity testing is used to derive symptoms as the main objective with mortality as a secondary objective (Paine and Marrs, 2000). From this data, LD<sub>50</sub> can be calculated as an indicator of acute response but LD<sub>50</sub> alone gives little information on chronic response. Sub-chronic toxicity studies of 90 day exposures are used to determine the chemical dose an animal can consume daily without any demonstrable effect (NOAEL), and to characterize the effects of the chemical when administered at doses above the NOAEL. Chronic toxicity studies measure the effect of doses below the NOAEL on the normal life span of the animal. Chronic studies are often used to determine if the substance causes “delayed” effects on reproduction, development or cancer. One dose in chronic studies should cause subtle signs of toxicity such as reduced weight gain or a minor physiological response. This dose is defined as the “lowest adverse effect level” (LOAEL). These classical toxicity studies using dosages in both effects and no effect range are designed to derive data to be applied to risk determination.

Toxicity testing has made great strides, ever increasing our ability to detect sensitive toxic endpoints. Routine haematology, blood biochemistry, histology, and cytology are being supplemented by sophisticated diagnostic equipment including ultrasound imaging, magnetic resonance imaging (MRI), and electron microscopy. New technologies are extremely sensitive at detecting effects at sub-clinical dosages. Molecular techniques (e.g. DNA Microarray) detect alterations at the molecular level and help elucidate modes of action. Toxic endpoints should, however, have a level of clinical significance. What should be the most sensitive toxicological parameter may soon have to be answered.

Most mycotoxin research has been designed to investigate toxic effects and therefore dosages used are in the toxic range. In such experiments the lowest experimental dose causing a toxic effect may be far greater than the threshold of the adverse effect and therefore overestimates the true LOAEL (Fig. 1). Furthermore, if an experimental dose falls into the no-effect range, it may be far below the threshold dose and therefore greatly underestimates the true NOAEL. These factors introduce variability and uncertainty in the estimation of NOAEL and LOAEL (USEPA, 1995).

As for all risk assessments, pet health risk assessment requires data on toxicity and exposure. Pet species are seldom used for toxicity studies and therefore data obtained from other species are used in the risk assessment for pets. This results in a level of uncertainty when extrapolating toxicity data from experimental animals to pet species (Faustman and Omenn, 2001).

The process of human health risk assessment (Covello and Merkhofer, 1993) can be applied to the risk determination in animals. In order to estimate the risk associated with mycotoxin exposure, we need to determine the dose a pet can consume in the food on a daily basis for their entire life with no adverse effect (i.e. NOAEL). This level can then be divided by an appropriate safety factor. Safety Factors (SF) (i.e. uncertainty factors) are numerical values applied to the NOAEL or other effect levels to account for any uncertainty in the data. The quotient derived is referred to as

![Illustration of the calculation of the NOAEL and LOAEL using a dose–response curve.](image-url)
the acceptable daily intake or ADI. A pet ADI could be determined as follows:

\[
\text{ADI( mg mycotoxin/kg BW) pet specific} = \frac{\text{NOAEL}_{\text{Rodent}}}{\text{SF}_{10}}.
\]

Uncertainty includes species extrapolation, the nature and severity of effect, differences in pet breeds, and variability in LOAEL estimation. SF’s could be adjusted according to epidemiological data on pets. Human SF numbers are often selected as a factor of 10, 100, or 1000 (Table 3) and set by the World Health Organization/Food and Agriculture Organization (WHO/FAO). Pet food SF’s could be set by the pet food industry to apply standard safety guidelines.

This process of combining the qualitative and quantitative aspects of toxicity and exposure to derive a quantitative level of risk is called “risk characterization” (Faustman and Omenn, 2001). To complete the process a safe pet dietary level (SPDL) can be determined using a pet specific food factor (FF). An example calculation is given for aflatoxin:

\[
\text{SPDL} = \frac{1.2 \mu g /\text{kg BW} \times 10 \text{ kg BW}}{10 \times (20 \mu g /\text{kg BW} \times 10 \text{ kg BW})} = 6 \mu g /\text{kg pet food}.
\]

The food factor is the amount of food consumed daily and accounts for the differences in the quantity of food consumed by different animal species. A safe pet dietary level would be equivalent to the human maximal permissible (tolerance) level in foods (MPL).

Risk management refers to the process by which policy actions are chosen to control hazards identified in the risk assessment/risk characterization processes (Faustman and Omenn, 2001; Covello and Merkhofer, 1993). Calculation of SPDL would provide producers with a pet specific maximal permissible (tolerance) level of mycotoxin in food. Managers would consider scientific evidence and risk estimates along with processing, engineering, economic, social and political factors in evaluating alternative options. This comprehensive approach would instil public confidence in the pet food industry.

6. Regulatory issues and preventative strategies

Considering that the intrinsic toxicological properties of a chemical cannot be altered, regulatory agencies consider exposure mitigation the only meaningful opportunity for risk reduction (NRC, 1993). Government regulations of mycotoxin contamination, however, are often compromised by the analytical detection limits, regional prevalence, as well as trade relationships amongst different countries instead of fulfilling the scientific approach of risk assessment and safety determination (Leung et al., 2006). Scientifically based regulations for the acceptable limit of mycotoxins in pet food would be beneficial. Strict regulations, however, would create greater competition with the human food chain resulting in increased pet food costs and decreased industry profits. It is also possible that the avoidance of severe regulations will promote mycotoxin outbreaks.

Pet food amelioration is often considered a practical solution for mycotoxin contamination. Food processing techniques such as sieving, washing, pearling, ozonation, and acid-based mold inhibition can reduce the mycotoxin content of cereal grains (Leung et al., 2006). Dietary supplementation with large neutral amino acids, antioxidants, and omega-3 polyunsaturated fatty acids as well as inclusion of mycotoxin-sequestering agents and detoxifying microbes may ameliorate the harmful effects of mycotoxins in contaminated pet food. Amelioration of pet food, however, should be used as an additional safety factor but not to replace the sound application of risk and safety determination.

The public has recently begun a shift to organic pet foods. The public perception is that organic foods are safer due to the lack of pesticide residues. In the case of mycotoxins, however, the avoidance of insecticides and fungicides may result in increased crop pest damage, fungal growth and mycotoxin production.

7. Conclusion

Mycotoxin contamination in pet food poses a serious health threat to pets. The health problems of pets are of a highly emotional concern and pet food safety is the responsibility of the pet food industry. Risk and safety determination is needed and must address many issues including sensitivity of toxic endpoints, multiple mycotoxin exposure, and pet food amelioration. More pet specific research is needed to better address the pet mycotoxin problem.
